Abstract

Concrete bridge deck deterioration is a leading cause for structurally deficient rating of bridges in the United States. To overcome this challenge, an innovative UHPC-NC composite deck panel with UHPC serving effectively as an overlay over normal concrete (NC) is proposed. The combination of UHPC and NC makes the proposed composite panel a durable and cost effective bridge deck solution. The influence of concrete strength and interface roughness on structural performance of the proposed composite bridge panel was investigated using a total of 60 slant shear tests and three flexural tests. The slant shear test results demonstrated that the bond strength of all five different interface textures was adequate, which was later confirmed by the flexural tests. Simple analytical models were developed to accurately predict the observed experimental behavior.

Résumé

L’endommagement des tabliers est une des causes majeures de déficience structurelle des ponts aux États-Unis. Pour régler ce problème, un panneau composite innovant BFUP/béton est proposé, dans lequel le BFUP sert de couche supérieure. La combinaison de BFUP et de béton standard fait du panneau composite proposé une solution de couverture de pont à la fois durable et économique. L’influence de la résistance du béton et de la rugosité de l’interface sur les performances du panneau a été estimée à l’aide de 60 essais de cisaillement et de trois essais de flexion. Les essais de cisaillement ont démontré que l’adhérence de chacun des cinq types de surface testés était suffisante, ce qui a ensuite été confirmé par les essais de flexion. Des modèles analytiques simples ont également été développés afin d’approcher avec précision le comportement expérimental mis en évidence.
1. INTRODUCTION

The combination of aging infrastructure, increasing number of structurally deficient or obsolete bridges, and continuous increase in traffic volume in the US demands rapid improvements to the nation’s bridge infrastructure with an emphasis on increasing bridge longevity. Currently, bridge deck deterioration is known to be a leading cause for poor rating of bridges in the U.S. Cracking of concrete, damage due to freeze/thaw cycles and corrosion of deck reinforcement due to penetration of chlorides from deicing salts are primary sources of deck deterioration and increased bridge maintenance costs. According to the Federal Highway Administration (FHWA), nearly $200-$300 billion dollars is needed to rehabilitate or replace all structurally deficient bridges in the nation [1]. Hence, Federal, State and municipal bridge engineers are seeking alternative ways to build better bridges, reduce travel times, and improve repair techniques, thereby reducing maintenance costs and increase bridge longevity. Additionally, owners are challenged with replacing critical bridge components, particularly bridge decks, during limited or overnight road closure periods. Consequently, there is an impending need to develop technologies, which are not only economical and durable, but can also be safely and rapidly implemented in practice.

Ultra High Performance Concrete (UHPC) is a self-leveling high strength concrete material with high durability [2] and dependable tensile strength [3] properties when compared to normal strength concrete (NC) used in today’s bridge construction. The unique combination of desirable durability properties and tensile strength of UHPC makes this an ideal material for minimizing deck cracking and associated bridge deterioration. Consequently, UHPC has gained significant momentum in terms of its utilization in bridge applications among several Department of Transportations (DOTs) and the Federal Highway Administration (FHWA).

A recently completed project entitled “Full depth UHPC precast waffle deck panels for bridge applications,” executed as part of Highways for LIFE program, confirmed the significant benefits of UHPC deck systems in terms of excellent structural performance and ease of construction [4]. However, the initial capital cost of the UHPC structures is significantly higher than the normal strength concrete, which may hinder the wider usage of UHPC waffle decks in bridges.

Realizing that the deck deterioration occurs due to formation of crack as well as penetration of deicing chemicals placed on the top surface, a composite bridge deck concept was motivated by overlaying a thin UHPC layer over a NC slab. This system not only provides a cost-effective solution by reducing the amount of UHPC by up to 50% in comparison to the waffle deck system, but it also yields a highly durable alternative to the traditional concrete deck system with high maintenance costs. However, a performance characterization of the composite deck system is essential to make this concept a reality for field applications. As illustrated in previous successful rehabilitation projects [5], the behavior connection interface plays a significant role on the overall structural and durability performance of the UHPC-NC composite deck system. Consequently, an experimental study was conducted at Iowa State University to understand the influence of several parameters such as normal concrete strength, interface roughness and curing condition on the interface shear-friction or bond behavior. The results and observations from this study are presented below.
2. EXPERIMENTAL PROGRAM

An experimental program with two phases of testing was executed. The goal of phase-1 testing was to estimate the bond strength between UHPC and NC for different interface textures and identify the most suitable interface for the UHPC-NC composite deck with due consideration to constructability and strength. The ASTM C 882 slant shear test [6] (Figure 1a) was used for this purpose. In Phase-2 testing, three point flexural tests were conducted on small segments of bridge decks to evaluate the performance of the composite section under combined flexural and shear loading. In both phases, the tests were intended to examine the performance of the connection interfaces under the maximum stresses expected for bridge decks using different load combinations.

2.1 Phase-1 testing: Slant shear tests

Based on a previous experimental study on the bond behavior of composite specimens incorporating UHPC [7] and the slant shear test concept [8], all interface tests in Phase-1 were completed using prismatic members as shown in Figure 1a. A test matrix consisting of five different textures and three concrete strengths was used to examine the feasibility and effects of different interface textures, concrete strength, casting sequence, and curing condition (fully cured vs. partially cured vs. wet conditions) on the shear friction behavior of the composite deck interface. To ensure easy constructability, mechanical connections such as shear studs across the UHPC and NC interface were not considered for experimental evaluation. The details of the test matrix are summarized in Table 1.

Each UHPC-NC composite specimen was 114 mm by 150 mm in cross-section, 600 mm long, and consisted of an inclined joint with different interface textures at the mid-height of the specimen. Based on the preliminary calculations and previous research, an inclination angle of 53.1 degrees to the horizontal axis was chosen to ensure [9] sliding along the interface. The joint interface surface was prepared using five different form-liners with varying roughness as shown in Figure 1b, which are typically used in the precast industry primarily for achieving architectural details. The use of form-liners ensured consistent interface roughness between units. The roughness of different form-liner patterns was chosen to replicate the different surface conditions expected during field applications. The degree of roughness in each case was established based on the macro texture depth, which varied from 2 mm to 6.5 mm for textures used in this study. In addition, the study investigated the influence of concrete strengths using 34 MPa, 52 MPa and 69 MPa mix designs.

The composite specimens were cast using standard flexural beam molds with appropriate texture and concrete mix. Depending upon the casting sequence and curing conditions, the interface texture was first created on either UHPC or normal concrete half-sections. For specimens with wet UHPC, the normal concrete with specified concrete strength was poured in the mold with the form-liner and the half-section was then cured for 28 days under ambient conditions. After the curing process, the normal concrete half sections were placed back into molds with the slant side up and were filled with UHPC. The final composite sections were cured under ambient conditions until the day of testing.

The composite specimens were subjected to uniaxial compression at the ends using a universal testing machine (see Figure 1a), subjecting the interface to shear stresses along the inclined joint interface. Several instruments, including displacement transducers and rotation meters, were used in the interface region to adequately characterize the performance, and closely monitor the movement along the inclined shear interface. Based on the observations from the initial tests, in specimens with deeper texture and lower concrete strength, the normal concrete section was strengthened using FRP wrap (see Figure 2a) to prevent compression splitting failure. All samples were tested to failure at the interface or through splitting of the normal concrete (NC) (see Figure 2b).
A total of 60 slant UHPC and NC interface specimens were tested to failure. The specimens were predominantly failed with sliding occurring along the interface. However, in a few specimens with deeper textures, even after the FRP retrofit, the splitting of the NC took place prior to sliding interface failure. The interface shear strength was calculated for all the specimens by dividing the maximum load along the inclined plane at failure by the contact area. This method gives a minimum value for the interface shear strength for the specimens failed in splitting of normal concrete and an exact value for those specimens failed along the interface. A comparison of the average interface shear capacity for each surface roughness and concrete strengths is presented in Figure 2c and Figure 2d, respectively. The bond strength generally increased with the increase of texture roughness and concrete strength. The casting sequence, however, did not significantly influence the bond strength. It was found that the bond strength developed for all textures would be adequate for applications in bridge decks as long the effects of differential shrinkage can be tolerated.
2.2 Phase-2 testing: Testing of UHPC-NC Composite Decks

Following the investigation of bond behavior using the slant shear tests on the composite test units, four UHPC-NC composite deck specimens with a texture depth varying from 2 mm to 6 mm were tested under combined flexural and shear loading. The textures along the interface in the test specimens were created using TR1, TR3 and TR4 form-liners as well as a hand broom finish on top of a NC surface. In each specimen, the dimensions of the NC portion were 2.74 m (length) x 0.81 m (width) x 203 mm (thickness), which represented a portion of the standard Iowa Department of Transportation (Iowa DOT) bridge deck [10]. All the specimens were constructed using concrete with a specified strength of 28 MPa. The measured compressive strengths of NC and UHPC at 28 days after casting were found to be 32 MPa and 107 MPa, respectively. The reinforcement in the NC portion was designed according to the AASHTO standards [11] and represented the reinforcement as included in current Iowa DOT bridge decks. The details and layout of the reinforcement is shown in Figure 3a. Consistent with the Iowa DOT standards, a 38-mm thickness was chosen for the overlay, which was wet UHPC and was placed on the rough surface of NC after 28 day curing.

Figure 3 Testing of UHPC-NC composite deck specimens
A three-point bending configuration as shown in Figure 3a was used to perform all of the load tests. The specimens were simply supported on rollers at a distance of 1.83 m apart. The load was applied at the center of the specimen with a hydraulic actuator. A 25 cm by 50 cm steel plate was used to distribute the load, which is in accordance with the AASHTO design guidelines to represent a standard truck wheel contact area. The measured force-displacement responses of the three specimens are shown in Figure 3b and the eventual damaged states of two specimens are shown in Figure 3c.

At the service-level loading of 95 kN, a few hairline cracks formed directly under the load. All specimens ultimately failed with the initiation of shear failure in the normal concrete portion of the composite deck at a load in the range of 320 to 347 kN, which is nearly 4.5 - 4.9 times the design service-level wheel load. The slip along the UHPC-NC interface was monitored using a 3D state-of-the-art optotrak system and no slip was observed at the interface until the initiation of the shear failure in the specimens. From the Figure 3b, it is clear that all three interfaces would be adequate for composite action. The broom finish specimen did not experience any significant ductility compared to other two specimens. Once the shear capacity of the composite deck was reached, delamination of the UHPC overlay was observed, which was appeared to be triggered by the shear cracking in the normal concrete. The shear crack in the normal concrete didn’t penetrate through the UHPC overlay. Instead, the crack propagated horizontally along the interface, causing delamination.

In the other two specimens, due to higher interface capacity resulted from deeper texture, the delamination due to shear cracking in normal concrete was triggered at larger deformation compared to the broom finish specimen. This resulted in wider shear cracks (see Figure 3c), larger shear deformations and yielding of the reinforcement leading higher displacement capacity at failure.

2.3 Analytical Modeling

The moment-curvature response of the composite slab section was calculated by modeling the section using a zero length fiber-based beam-column element in SeismoStruct software [12]. The beam cross-section is discretized into a series of fibers in both directions. The stress-strain behavior of fibers was represented using appropriate uniaxial material models available in the analysis software. The longitudinal steel, normal concrete and UHPC were modeled respectively using stl_bl, con_ma and con_tl material models [12]. Tension behavior of the normal concrete is modeled using softening model with a peak tensile capacity of 2.1 MPa.

The comparison of experimental and analytical force-displacement response for two specimens is shown in Figure 4. From Figure 4, it is clear that the analytical model captured the observed force-displacement response and initial stiffness of the composite system accurately. The predicted ultimate moment capacity of the composite system was within 2% of the measured value.
3. CONCLUSIONS

An economical and durable solution for rehabilitation and replacement of deteriorating bridge decks is proposed using a composite UHPC-NC deck system. Two phases of experimental testing, focusing on the interface behavior under combined shear-compression, shear-flexure loading was completed. The influence of design parameters such as interface texture, concrete strength and casting sequence on the composite action was evaluated. Based on the observations from the experimental testing and analytical modeling, the following conclusions are drawn:

1) Based on the slant-shear tests, a minimum roughness of 2 mm was sufficient to develop adequate bond strength between UHPC and NC interface under combined shear and compression loading.

2) The bond strength between UHPC and NC increases with the increase in interface roughness and concrete strength. The casting sequence did not have any significant influence on the bond strength.

3) Based on the flexural tests on composite slabs, it is clear that UHPC can be used as a durable overlay in bridge decks with a 2 mm minimum roughness for the UHPC and NC interface.

4) The composite section behavior can be accurately calculated using analytical models with fiber-based beam elements.
ACKNOWLEDGEMENTS

The authors would like to thank Iowa DOT for sponsoring the research presented summarized in this paper. In addition, the authors are indebted to Vic Perry of Lafarge North America for providing UHPC material. The assistance provided by Doug Wood, Structural Lab Manager at Iowa State University and Owen Steffens in completing the tests is greatly appreciated.
